Abstract. We present an approach to path planning for humanoid robots that computes dynamically-stable, collision-free trajectories from full-body posture goals. Given a geometric model of the environment and a statically-stable desired posture, we search the configuration space of the robot for a collision-free path that simultaneously satisfies dynamic balance constraints. We adapt existing randomized path planning techniques by imposing balance constraints on incremental search motions in order to maintain the overall dynamic stability of the final path. A dynamics filtering function that constrains the ZMP (zero moment point) trajectory is used as a post-processing step to transform statically-stable, collision-free paths into dynamically-stable, collision-free trajectories for the entire body. Although we have focused our experiments on biped robots with a humanoid shape, the method generally applies to any robot subject to balance constraints (legged or not). The algorithm is presented along with computed examples using both simulated and real humanoid robots.

Keywords: Motion Planning, Humanoid Robots, Dynamics, Obstacle Avoidance

1. Introduction

Recently, significant progress has been made in the design and control of humanoid robots, particularly in the realization of dynamic walking in several full-body humanoids (Hirai, 1997; Yamaguchi et al., 1998; Nagasaka et al., 1999). As the technology and algorithms for real-time 3D vision and tactile sensing improve, humanoid robots will be able to perform tasks that involve complex interactions with the environment (e.g. grasping and manipulating objects). The enabling software for such tasks includes motion planning for obstacle avoidance, and integrating planning with visual and tactile sensing data.

Figure 1. Dynamically-stable motion for retrieving an object (*top*: simulation, *bottom*: real robot hardware).

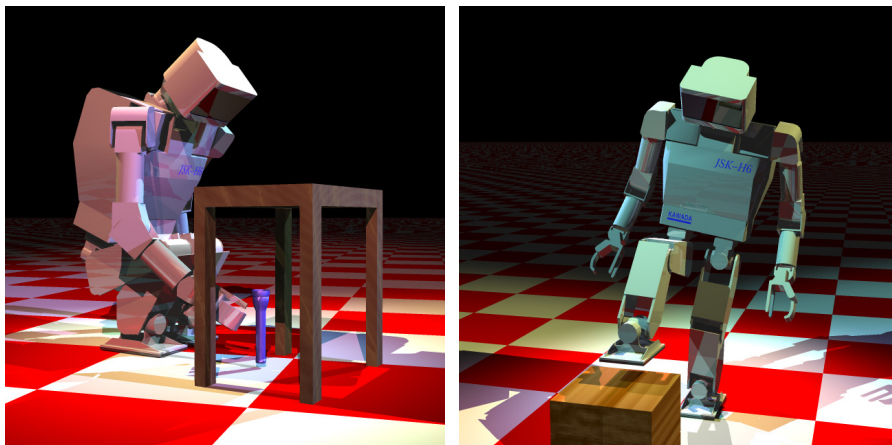

Figure 2. Simulation snapshots of computed full-body trajectories.

To facilitate the deployment of such software, we are currently developing a graphical simulation environment for testing and debugging (Kuffner et al., 2000a). Figure 2 shows images produced by our simulation environment.

This paper presents an algorithm for automatically generating collision-free dynamically-stable motions from full-body posture goals. It expands upon the preliminary algorithm developed in (Kuffner et al., 2000b), and has been tested and verified on the humanoid robot hardware platform “H6”. Our approach is to adapt techniques from an existing, successful path planner (Kuffner and LaValle, 2000) by imposing balance constraints upon incremental motions used during the search. Provided the initial and goal configurations correspond to collision-free, statically-stable body postures, the path returned by the planner can be transformed into a collision-free and dynamically-stable trajectory for the entire body. To the best of our knowledge, this represents the first general motion planning algorithm for humanoid robots that has also been experimentally confirmed on real humanoid robot hardware.

Although the current implementation of the planner is limited to body posture goals, and a fixed position for either one or both feet, we hope to extend the method to handle more complex body posture repositioning. We believe that through the use of such kinds of task-level planning algorithms and interactive simulation software, the current and future capabilities of humanoid and other complex robotic systems can be improved.

The rest of this paper is organized as follows: Section 2 gives an overview of previous work, Section 3 describes the planning algorithm, Section 4 presents experimental results, and Section 5 contains a summary and outlines some areas of future work.

2. Background

Due to the complexity of motion planning in its general form (Reif, 1979), the use of complete algorithms (Schwartz and Sharir, 1983; Canny, 1988) is limited to low-dimensional configuration spaces. Moreover, these algorithms are extremely difficult to implement even for simple problems (Hirukawa and Papegay, 2000; Hirukawa et al., 2001). This has motivated the use of heuristic algorithms, many of which employ randomization (e.g., (Barraquand and Latombe, 1990; Horsch et al., 1994; Amato and Wu, 1996; Kavraki et al., 1996; Hsu et al., 1997; Mazer et al., 1998; Boor et al., 1999; Kuffner and LaValle, 2000; Bohlin and Kavraki, 2000)). Although these methods are incomplete, many have

been shown to find paths in high-dimensional configuration spaces with high probability.

Motion planning for humanoid robots poses a particular challenge. Developing practical motion planning algorithms for humanoid robots is a daunting task given that humanoid robots typically have 30 or more degrees of freedom. The problem is further complicated by the fact that humanoid robots must be controlled very carefully in order to maintain overall static and dynamic stability. These constraints severely restrict the set of allowable configurations and prohibit the direct application of existing motion planning techniques. Although efficient methods have been developed for maintaining dynamic balance for biped robots (Raibert, 1986; Vukobratovic et al., 1990; Pratt and Pratt, 1999; Kagami et al., 2000), none consider obstacle avoidance.

2.1. MOTION PLANNING WITH DYNAMIC CONSTRAINTS

Motion planning algorithms that account for system dynamics typically approach the problem in one of two ways:

1. **Decoupled Approach:** Solving the problem by first computing a kinematic path, and subsequently transforming the path into a dynamic trajectory.
2. **State-space Formulation:** Searching the system state-space directly by reasoning about the possible controls that can be applied.

The method presented in this paper adopts the first approach. Other methods using one of these two planning strategies have been developed for off-road vehicles (Shiller and Gwo, 1991; Cherif and Laugier, 1995), free-flying 2D and 3D rigid bodies (LaValle and Kuffner, 1999; LaValle and Kuffner, 2000), helicopters and satellites (Frazzoli et al., 1999), and for a free-flying disc among moving obstacles (Kindel et al., 2000). None of these previous methods have yet been applied to complex articulated models such as humanoid robots. One notable exception is the VHRP simulation software under development (Nakamura and *et. al.*, 2000), which contains a path planner that limits the active body degrees of freedom for humanoid robots for simultaneous obstacle avoidance and balance control. Since the space of possible computed motions is limited however, this planner is not fully general.

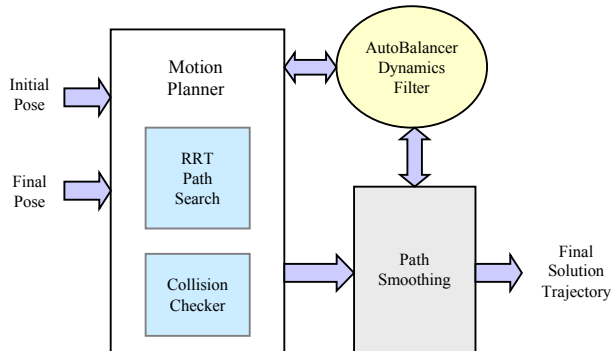

Figure 3. Algorithm Overview.

3. Dynamically-stable Motion Planning

Our approach is to adapt a variation of the randomized planner described in (Kuffner and LaValle, 2000) to compute full-body motions for humanoid robots that are both dynamically-stable and collision-free. The first phase computes a statically-stable, collision-free path, and the second phase smooths and transforms this path into a dynamically-stable trajectory for the entire body. An block diagram of the major software components are shown in Figure 3.

The planning method (RRT-Connect) and its variants utilize Rapidly-exploring Random Trees (RRTs) (LaValle, 1998; LaValle and Kuffner, 2000) to connect two search trees, one from the initial configuration and the other from the goal. This method has been shown to be efficient in practice and converge towards a uniform exploration of the search space. For the second phase, the collision checker is used in conjunction with a dynamics filter function “*AutoBalancer*” (Kagami et al., 2000) in order to generate a final dynamically-stable trajectory that is also collision-free.

3.1. ROBOT MODEL AND ASSUMPTIONS

We have based our experiments on an approximate model of the H6 humanoid robot (see Figure 1), including the kinematics and dynamic properties of the links. Although we have focused our experiments on biped robots with a humanoid shape, the algorithm generally applies to any robot subject to balance constraints (legged or not). Aside from the existence of the dynamic model, we make the following assumptions:

1. **Environment model:** We assume that the robot has access to a 3D model of the surrounding environment to be used for collision checking. This model could have been obtained through sensors

such as laser rangefinding or stereo vision, or given directly in advance.

2. **Initial posture:** The robot is currently balanced in a collision-free, statically-stable configuration supported by either one or both feet.
3. **Goal posture:** A full-body goal configuration that is both collision-free and statically-stable is specified. The goal posture may be given explicitly by a human operator, or computed via inverse kinematics or other means. (e.g. for extending a limb towards a target location or object).
4. **Support base:** The location of the supporting foot (or *feet* in the case of dual-leg support) does not change during the planned motion.

3.2. PROBLEM FORMULATION

Our problem will be defined in a 3D world \mathcal{W} in which the robot moves. \mathcal{W} is modeled as the Euclidean space \mathbb{R}^3 (\mathbb{R} is the set of real numbers).

3.2.1. Robot

Let the robot \mathcal{A} be a finite collection of p rigid links \mathcal{L}_i ($i = 1, \dots, p$) organized in a kinematic hierarchy with Cartesian frames \mathcal{F}_i attached to each link. We denote the position of the center of mass c_i of link \mathcal{L}_i relative to \mathcal{F}_i . A *pose* of the robot is denoted by the set $\mathcal{P} = \{T_1, T_2, \dots, T_p\}$, of p relative transformations for each of the links \mathcal{L}_i as defined by the frame \mathcal{F}_i relative to its parent link's frame. The *base* or *root* link transformation T_1 is defined relative to some world Cartesian frame \mathcal{F}_{world} . Let n denote the number of generalized coordinates or *degrees of freedom* (DOFs) of \mathcal{A} . A *configuration* is denoted by $q \in \mathcal{C}$, a vector of n real numbers specifying values for each of the generalized coordinates of \mathcal{A} . Let \mathcal{C} be the *configuration space* or \mathcal{C} -space of \mathcal{A} . \mathcal{C} is a space of dimension n .

3.2.2. Obstacles

The set of obstacles in the environment \mathcal{W} is denoted by \mathcal{B} , where \mathcal{B}_k ($k = 1, 2, \dots$) represents an individual obstacle. We define the *\mathcal{C} -obstacle region* $\mathcal{CB} \subset \mathcal{C}$ as the set of all configurations $q \in \mathcal{C}$ where one or more of the links of \mathcal{A} intersect (are in collision) with another link of \mathcal{A} , or any of the obstacles \mathcal{B}_k . We also regard configurations $q \in \mathcal{C}$ where one or more *joint limits* are violated as part of the \mathcal{C} -obstacle region \mathcal{CB} . The open subset $\mathcal{C} \setminus \mathcal{CB}$ is denoted by \mathcal{C}_{free} and its closure

by $cl(\mathcal{C}_{free})$, and it represents the *space of collision-free configurations* in \mathcal{C} of the robot \mathcal{A} .

3.2.3. Balance and Torque Constraints

Let $\mathcal{X}(q)$ be a vector relative to \mathcal{F}_{world} representing the global position of the center of mass of \mathcal{A} while in the configuration q . A configuration q is *statically-stable* if: 1) the projection of $\mathcal{X}(q)$ along the gravity vector g lies within the area of support \mathcal{SP} (i.e. the convex hull of all points of contact between \mathcal{A} and the support surface in \mathcal{W}), and 2) the joint torques Γ needed to counteract the gravity-induced torques $G(q)$ do not exceed the maximum torque bounds Γ_{max} . Let $\mathcal{C}_{stable} \subset \mathcal{C}$ be the subset of *statically-stable configurations* of \mathcal{A} . Let $\mathcal{C}_{valid} = \mathcal{C}_{stable} \cap \mathcal{C}_{free}$ denote the subset of configurations that are both *collision-free* and *statically-stable* postures of the robot \mathcal{A} . \mathcal{C}_{valid} is called the set of *valid configurations*.

3.2.4. Solution Trajectory

Let $\tau : \mathcal{I} \mapsto \mathcal{C}$ where \mathcal{I} is an interval $[t_0, t_1]$, denote a motion trajectory or *path* for \mathcal{A} expressed as a function of time. $\tau(t)$ represents the configuration q of \mathcal{A} at time t , where $t \in \mathcal{I}$. A trajectory τ is said to be *collision-free* if $\tau(t) \in \mathcal{C}_{free}$ for all $t \in \mathcal{I}$. A trajectory τ is said to be both *collision-free* and *statically-stable* if $\tau(t) \in \mathcal{C}_{valid}$ for all $t \in \mathcal{I}$. Given $q_{init} \in \mathcal{C}_{valid}$ and $q_{goal} \in \mathcal{C}_{valid}$, we wish to compute a continuous motion trajectory τ such that $\forall t \in [t_0, t_1], \tau(t) \in \mathcal{C}_{valid}$, and $\tau(t_0) = q_{init}$ and $\tau(t_1) = q_{goal}$. We refer to such a trajectory as a *statically-stable trajectory*.

3.2.5. Dynamic Stability

Theoretically, any statically-stable trajectory can be transformed into a dynamically-stable trajectory by arbitrarily slowing down the motion. For these experiments, we utilize the online balance compensation scheme “*AutoBalancer*” described in (Kagami et al., 2000) as a method of generating a final dynamically-stable trajectory after path smoothing (see Section 3.5).

3.2.6. Planning Query

Note that in general, if a dynamically-stable solution trajectory exists for a given path planning query, there will be many such solution trajectories. Let Φ denote the set of all dynamically-stable solution trajectories for a given problem. A *planning query* is as follows:

$$Planner(\mathcal{A}, \mathcal{B}, q_{init}, q_{goal}) \longrightarrow \tau \quad (1)$$

Given a model of the robot \mathcal{A} , obstacles in the environment \mathcal{B} , and the initial and goal postures, the planner returns a solution trajectory

$\tau \in \Phi$. If the planner fails to find a solution, τ will be empty (a null trajectory).

Currently, we require the planning software to compute only one solution (it returns the first one it finds). However, given a trajectory evaluation function $\Gamma(\tau)$, the planner could compute a set of candidate trajectories $\bar{\Phi}$ within a given time period, and then select the best one τ_{best} returned so far: $\tau_{best} = \min \Gamma(\tau), \tau \in \bar{\Phi}$.

3.3. PATH SEARCH

Unfortunately, there are no currently known methods for explicitly representing \mathcal{C}_{valid} . The obstacles are modeled completely in \mathcal{W} , thus an explicit representation of \mathcal{C}_{free} is also not available. However, using a collision detection algorithm, a given $q \in \mathcal{C}$ can be tested to determine whether $q \in \mathcal{C}_{free}$. Testing whether $q \in \mathcal{C}_{stable}$ can also be checked verifying that the projection of $\mathcal{X}(q)$ along g is contained within the boundary of \mathcal{SP} , and that the torques Γ needed to counteract gravitational torques $G(q)$ do not exceed Γ_{max} .

3.3.1. Distance Metric

As with the most planning algorithms in high-dimensions, a metric ρ is defined on \mathcal{C} . The function $\rho(q, r)$ returns some measure of the distance between the pair of configurations q and r . Some axes in \mathcal{C} are weighted relative to each other, but the general idea is to measure the ‘‘closeness’’ of pairs of configurations with a positive scalar function.

For our humanoid robot models, we employ a metric that assigns higher relative weights to the generalized coordinates of links with greater mass and proximity to the trunk (torso):

$$\rho(q, r) = \sum_{i=1}^n w_i \|q_i - r_i\| \quad (2)$$

This choice of metric function attempts to heuristically encode a general relative measure of how much the variation of an individual joint parameter affects the overall body posture. Additional experimentation is needed in order to evaluate the efficacy of the many different metric functions possible.

3.3.2. Planning Algorithm

We employ a randomized search strategy based on Rapidly-exploring Random Trees (RRTs) (LaValle and Kuffner, 1999; Kuffner and LaValle, 2000). For implementation details and analysis of RRTs, the reader is referred to the original papers or a summary in (LaValle and Kuffner, 2000). In (Kuffner et al., 2000b), we developed an RRT variant the

generates search trees using a dynamics filter function to guarantee dynamically-stable trajectories along each incremental search motion.

The algorithm described in this article is more general and efficient than the planner presented in (Kuffner et al., 2000b), since it does not require the use of a dynamics filtering function during the path search phase. In addition, it can handle either single or dual-leg support postures, and the calculated trajectories have been verified using real robot hardware.

The basic idea is the same as the RRT-Connect algorithm described in (Kuffner and LaValle, 2000). The key difference is that *instead of searching \mathcal{C} for a solution path that lies within \mathcal{C}_{free} , the search is performed in \mathcal{C}_{stable} for a solution path that lies within \mathcal{C}_{valid}* . In particular, we modify the planner variant that employs symmetric calls to the *EXTEND* function as follows:

1. The *NEW_CONFIG* function in the *EXTEND* operation checks balance constraints in addition to checking for collisions with obstacles (i.e. $q_{new} \in \mathcal{C}_{valid}$).
2. Rather than picking a purely random configuration $q_{rand} \in \mathcal{C}$ at every planning iteration, we pick a random configuration that also happens to correspond to a statically-stable posture of the robot (i.e. $q_{rand} \in \mathcal{C}_{stable}$).

Pseudocode for the complete algorithm is given in Figure 5. The main planning loop involves performing a simple iteration in which each step attempts to extend the RRT by adding a new vertex that is biased by a randomly-generated, statically-stable configuration (see Section 3.4). *EXTEND* selects the nearest vertex already in the RRT to the given configuration, q , with respect to the distance metric ρ . Three situations can occur: *Reached*, in which q is directly added to the RRT, *Advanced*, in which a new vertex $q_{new} \neq q$ is added to the RRT; *Trapped*, in which no new vertex is added due to the inability of *NEW_CONFIG* to generate a path segment towards q that lies within \mathcal{C}_{valid} .

NEW_CONFIG attempts to make an incremental motion toward q . Specifically, it checks for the existence of a short path segment $\delta = (q_{near}, q_{new})$ that lies entirely within \mathcal{C}_{valid} . If $\rho(q, q_{near}) < \epsilon$, where ϵ is some fixed incremental distance, then q itself is used as the new configuration q_{new} at the end of the candidate path segment δ (i.e. $q_{new} = q$). Otherwise, q_{new} is generated at a distance ϵ along the straight-line from q_{near} to q .¹ All configurations q' along the path segment δ are

¹ A slight modification must be made for the case of dual-leg support. In this case, when interpolating two stable configurations, inverse kinematics for the leg

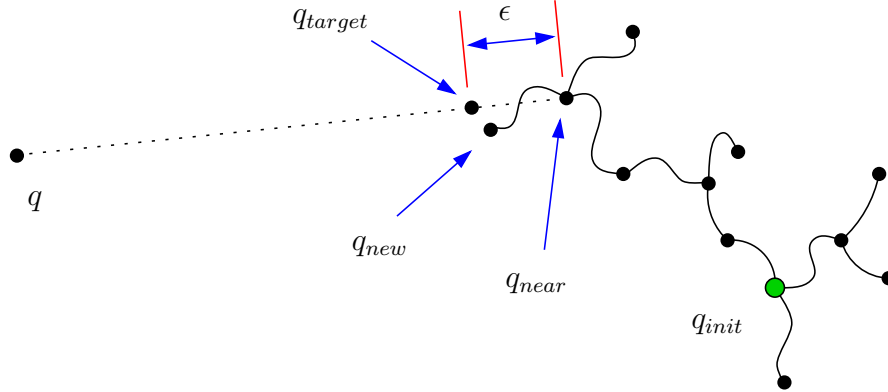

Figure 4. The modified EXTEND operation.

checked for collision, and tested whether balance constraints are satisfied. Specifically, if $\forall q' \in \delta(q_{near}, q_{new}), q' \in \mathcal{C}_{valid}$, then *NEW_CONFIG* succeeds, and q_{new} is added to the tree \mathcal{T} . In this way, the planner uses uniform samples of \mathcal{C}_{stable} in order to grow trees that lie entirely within \mathcal{C}_{valid} .

3.3.3. Convergence and Completeness

Although not given here, arguments similar to those presented in (Kuffner and LaValle, 2000) and (LaValle and Kuffner, 2000) can be constructed to show uniform coverage and convergence over \mathcal{C}_{valid} .

Ideally, we would like to build a *complete* planning algorithm. That is, the planner always returns a solution trajectory if one exists, and indicates failure if no solution exists. As mentioned in Section 2, implementing a practical complete planner is a daunting task for even low-dimensional configuration spaces (see (Hirukawa and Papegay, 2000)). Thus, we typically trade off completeness for practical performance by adopting heuristics (e.g. randomization).

The planning algorithm implemented here is incomplete in that it returns failure after a preset time limit is exceeded. Thus, if the planner returns failure, we cannot conclude whether or not a solution exists for the given planning query, only that our planner was unable to find one in the allotted time. Uniform coverage and convergence proofs, though only theoretical, at least help to provide some measure of confidence that when an algorithm fails to find a solution, it is likely that no solution exists. This is an area of ongoing research.

is used to force the relative position between the feet to remain fixed. The same technique is also used for generating random statically-stable dual-leg postures (see Section 3.4).

```

EXTEND( $\mathcal{T}, q$ )
1   $q_{near} \leftarrow \text{NEAREST\_NEIGHBOR}(q, \mathcal{T});$ 
2  if NEW_CONFIG( $q, q_{near}, q_{new}$ ) then
3     $\mathcal{T}.\text{add\_vertex}(q_{new});$ 
4     $\mathcal{T}.\text{add\_edge}(q_{near}, q_{new});$ 
5    if  $q_{new} = q$  then Return Reached;
6    else Return Advanced;
7  Return Trapped;

```

```

RRT_CONNECT_STABLE( $q_{init}, q_{goal}$ )
1   $\mathcal{T}_a.\text{init}(q_{init}); \mathcal{T}_b.\text{init}(q_{goal});$ 
2  for  $k = 1$  to  $K$  do
3     $q_{rand} \leftarrow \text{RANDOM\_STABLE\_CONFIG}();$ 
4    if not (EXTEND( $\mathcal{T}_a, q_{rand}$ ) = Trapped) then
5      if (EXTEND( $\mathcal{T}_b, q_{rand}$ ) = Reached) then
6        Return PATH( $\mathcal{T}_a, \mathcal{T}_b$ );
7    SWAP( $\mathcal{T}_a, \mathcal{T}_b$ );
8  Return Failure

```

3.4. RANDOM STATICALLY-STABLE POSTURES

For our algorithm to work, we require a method of generating random statically-stable postures (i.e. random point samples of \mathcal{C}_{stable}). Although it is trivial to generate random configurations in \mathcal{C} , it is not so easy to generate them in \mathcal{C}_{stable} , since it encompasses a much smaller subset of the configuration space.

In our current implementation, a set $\mathcal{Q}_{stable} \subset \mathcal{C}_{stable}$ of N samples of \mathcal{C}_{stable} is generated as a preprocessing step. This computation is specific to a particular robot and support-leg configuration, and need only be performed once. Different collections of stable postures are saved to files and can be loaded into memory when the planner is initialized. Although stable configurations could be generated “on-the-fly” at the same time the planner performs the search, pre-calculating \mathcal{Q}_{stable} is preferred for efficiency. In addition, multiple stable-configuration set files for a particular support-leg configuration can be saved independently. If the planner fails to find a path after all N samples have been

removed from the currently active \mathcal{Q}_{stable} set, a new one can be loaded with different samples.²

3.4.1. *Single-leg Support Configurations*

For configurations that involve balancing on only one leg, the set \mathcal{Q}_{stable} can be populated as follows:

1. The configuration space of the robot \mathcal{C} is sampled by generating a random body configuration $q_{rand} \in \mathcal{C}$.³
2. Assuming the right leg is the supporting foot, q_{rand} is tested for membership in \mathcal{C}_{valid} (i.e. static stability, no self-collision, and joint torques below limits).
3. Using the same sample q_{rand} , a similar test is performed assuming the left leg is the supporting foot.
4. Since most humanoid robots have left-right symmetry, if $q_{rand} \in \mathcal{C}_{valid}$ in either or both cases, we can “mirror” q_{rand} to generate stable postures for the opposite foot.

3.4.2. *Dual-leg Support Configurations*

It is slightly more complicated to generate statically-stable body configurations supported by both feet at a given fixed relative position. In this case, populating \mathcal{Q}_{stable} is very similar to the problem of sampling the configuration space of a constrained closed-chain system (e.g. closed-chain manipulator robots or molecular conformations (LaValle et al., 1999; Han and Amato, 2000)). The set \mathcal{Q}_{stable} is populated with fixed-position dual-leg support postures as follows:

1. As in the single-leg case, the configuration space of the robot \mathcal{C} is sampled by generating a random body configuration $q_{rand} \in \mathcal{C}$.
2. Holding the right leg fixed at its random configuration, inverse kinematics is used to attempt to position the left foot at the required relative position to generate the body configuration q_{right} . If it succeeds, then q_{right} is tested for membership in \mathcal{C}_{valid} .

² Since our humanoid robot H6 has 33 DOF, storing a 4-byte float for each joint variable corresponds to roughly 1.2MB of storage per $N = 10,000$ sample configurations. However, this memory usage can be significantly reduced by adopting fixed-point representations for the joint variables. This has not been implemented in our current planner.

³ This can be done by simply independently sampling all joint variables. Alternatively, one can assemble body configurations from collections of canonical postures for each limb. Our implementation uses the latter approach, since sampling all joints independently tends to generate rather strange or unnatural postures.

Figure 6. Dual-leg and single-leg stable postures for H5 (perspective view).

3. An identical procedure is performed to generate q_{left} by holding the left leg fixed at its random configuration derived from q_{rand} , using inverse kinematics to position the right leg, and testing for membership in \mathcal{C}_{valid} .
4. If either $q_{right} \in \mathcal{C}_{valid}$ or $q_{left} \in \mathcal{C}_{valid}$, and the robot has left-right symmetry, additional stable postures can be derived by mirroring the generated stable configurations.

A sample series of dual-leg and single-leg stable postures for the H5 humanoid robot are shown in Figure 6 (perspective view), Figure 7 (front view), and Figure 8 (left view). Sample dual-leg and single-leg stable postures for the H6 humanoid robot are shown in Figure 9.

3.5. TRAJECTORY GENERATION

If successful, the path search phase returns a continuous sequence of collision-free, statically-stable body configurations. All that remains is to calculate a final solution trajectory τ that is dynamically-stable and collision-free. Theoretically, any given statically-stable trajectory can be transformed into a dynamically-stable trajectory by arbitrarily slowing down the motion. However, we can almost invariably obtain a smoother and shorter trajectory by performing the following two steps:

Figure 7. Dual-leg and single-leg stable postures for H5 (front view).

Figure 8. Dual-leg and single-leg stable postures for H5 (left view).

Figure 9. Dual-leg and single-leg stable postures for H6 (perspective view).

3.5.1. Smoothing

We smooth the raw path by making several passes along its length, attempting to replace portions of the path between selected pairs of configurations by straight-line segments in \mathcal{C}_{valid} .⁴ This step typically eliminates any potentially unnatural postures along the random path (e.g. unnecessarily large arm motions). The resulting smoothed path is transformed into an input trajectory using a minimum-jerk model (Flash and Hogan, 1985).

3.5.2. Filtering

A dynamics filtering function is used in order to output a final, dynamically-stable trajectory. We use the online balance compensation scheme described in (Kagami et al., 2000), which enforces constraints upon the center of gravity projection and zero moment point (ZMP) trajectory in order to maintain overall dynamic stability. The overall body posture is adjusted iteratively in order to compensate for any violation of the constraints.

The constrained output trajectory is calculated by posing the balance compensation problem as an optimization problem under reasonable assumptions about the input motion trajectory (for details, see (Kagami et al., 2000)). The output configuration of the filter is guaranteed to lie in \mathcal{C}_{stable} . Collision-checking is used to verify that the final output trajectory lies in \mathcal{C}_{valid} . The filter is invoked repeatedly: if a collision is detected, the speed of the input trajectory is made slower.

⁴ When interpolating dual-leg configurations, inverse kinematics is used to keep the relative position of the feet fixed.

Figure 10. Dynamically-stable planned trajectory for a crouching motion.

If no collision is detected, the speed is increased, filtered, and checked again for collision.

Although this method has generated satisfactory results in our experiments, it is by no means the only option. Other ways of generating dynamically-stable trajectories from a given input motion are also potentially possible to apply here (e.g. (Yamaguchi et al., 1998; Nakamura and Yamane, 2000)). It is also possible to employ variational techniques, or apply algorithms for computing time-optimal trajectories (Shiller and Dubowsky, 1991). Calculating the *globally-optimal trajectory* according to some cost functional based on the obstacles and the dynamic model is an open problem, and an area of ongoing research.

4. Experiments

This section presents some preliminary experiments performed on a 270 MHz SGI O2 (R12000) workstation. We have implemented a prototype planner in C++ that runs within a graphical simulation environment (Kuffner et al., 2000a). An operator can position individual joints or use inverse kinematics to specify body postures for the virtual robot. The filter function can be run interactively to ensure that the goal configuration is statically-stable. After specifying the goal, the planner is invoked to attempt to compute a dynamically-stable trajectory connecting the goal configuration to the robot’s initial configuration (assumed to be a collision-free, stable posture).

Figure 10 shows a computed dynamically-stable motion for the H5 robot moving from a neutral standing position to a low crouching posture.

We have tested the output trajectories calculated by the planner on an actual humanoid robot hardware platform. The “H6” humanoid robot (33-DOF) is 137cm tall and weighs 51kg (including 4kg of batteries).

Several full-body motion trajectories were planned. Figure 1 shows a computed dynamically-stable motion for the H6 robot moving from

Figure 11. Dynamically-stable crouching trajectory for retrieving an object from beneath an obstacle

a neutral standing position to a low crouching position in order to retrieve an object from beneath a chair. Figure 11 shows a different view of the real robot executing the same motion. This motion was executed “open-loop” on the robot, but was accurate enough to allow the robot to successfully pick up the object from the floor. In the future, we hope to use the stereo vision system mounted in the robot’s head in order to visually servo such object manipulation motions.

Two single-leg examples were calculated. Figure 12 shows a motion for positioning the right leg above the top of an obstacle while balancing on the left leg. The motion in Figure 13 was not executed on the real robot, but is interesting in that it involves reaching for an object placed on top of a cabinet while avoiding both the cabinet and the shelves behind the robot. The robot is required to balance on one leg in order to extend the arm far enough to reach the obstacle on the table.

Each of the scenes contains over 9,000 triangle primitives. The 3D collision checking software used for these experiments was the RAPID library based on OBB-Trees developed by the University of North Carolina (Gottschalk et al., 1996). The total wall time elapsed in solving these queries ranges from under 30 seconds to approximately 11 minutes. A summary of the computation times for repeated runs of 25 trials each is shown in Table I.

Figure 12. Positioning the right foot above an obstacle while balancing on the left leg. (*top*: simulation, *bottom*: actual hardware).

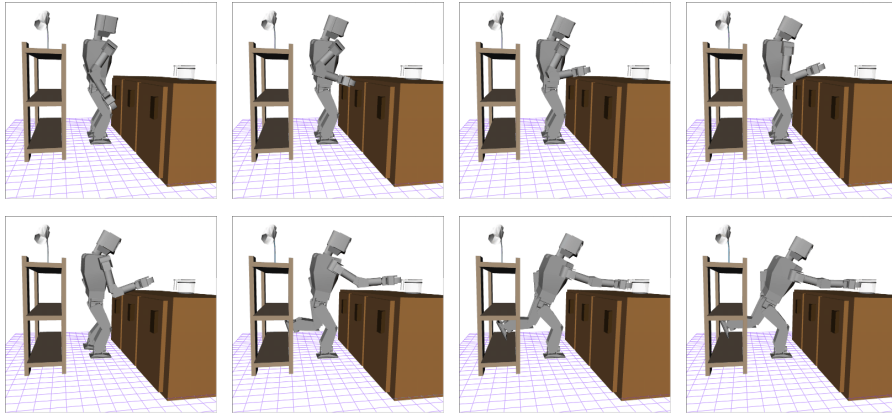

Figure 13. Reaching for an object atop a cabinet while avoiding obstacles and balancing on the right leg.

Table I. Performance statistics ($N = 25$ trials).

Task Description	Computation Time (seconds)			
	min	max	avg	stdev
H5 - Crouch near table	176	620	304	133
H6 - Reach under chair	171	598	324	138
H6 - Lift leg over box	26	103	48	21
H6 - Reach over table	194	652	371	146

5. Discussion

This paper presents an algorithm for computing dynamically-stable collision-free trajectories given full-body posture goals. Although we have focused our experiments on biped robots with a humanoid shape, the algorithm is general and can be applied to any robot subject to balance constraints (legged or not). There are many potential uses for such software, with the primary one being a high-level control interface for automatically computing motions to solve complex tasks for humanoid robots that involve simultaneous obstacle-avoidance and balance constraints.

The limitations of the algorithm form the basis for our future work:

- the current implementation of the planner can only handle a fixed position for either one or both feet. The ability to change the base of support, or perform “dynamic” transitions such as jumping or hopping from one foot to the other would be an exciting improvement.
- The effectiveness of different configuration space distance metrics needs to be investigated.
- We currently have no method for integrating visual or tactile feedback.

Acknowledgements

We thank Fumio Kanehiro and Yukiharu Tamiya for their efforts in developing the AutoBalancer software library. We are grateful to Hirohisa Hirukawa and Steven LaValle for helpful discussions. This research is supported in part by a Japan Society for the Promotion of Science (JSPS) Postdoctoral Fellowship for Foreign Scholars in Science and Engineering, and by JSPS Grant-in-Aid for Research for the Future (JSPS-RFTF96P00801).
